(Dated: November 22, 2009)

The effect of a magnetic field on the dipole echo amplitude in glasses (at temperatures of about 10 mK) induced by the dipole-dipole interaction of nuclear spins has been theoretically studied. It has been shown that a change in the positions of nuclear spins as a result of tunneling and their interaction with the external magnetic field E_H lead to a nonmonotonic magnetic field dependence of the dipole echo amplitude. The approximation that the nuclear dipole-dipole interaction energy E_d is much smaller than the Zeeman energy E_H has been found to be valid in the experimentally important cases. It has been shown that the dipole echo amplitude in this approximation may be described by a simple universal analytic function independent of the microscopic structure of the two-level systems. An excellent agreement of the theory with the experimental data has been obtained without fitting parameters (except for the unknown echo amplitude).

I. INTRODUCTION

Glasses at temperatures below 1 K are known to exhibit a number of universal properties almost independent of their composition and fundamentally different from the properties of similar crystals. These properties are traditionally described within the model of two-level systems (TLS's) [1]. One of these properties is a two-pulse electric dipole echo in glasses, which is the delayed response to two high-frequency electromagnetic pulses.

When a glass is subjected to two rf pulses with a frequency of about 1 GHz separated by a time interval τ much longer than the pulse length, one can observe a response in the glass polarization at time τ after the second pulse. Especially interesting is the pronounced nonmonotonic magnetic field dependence of the two-pulse echo amplitude observed at temperatures of 10 mK in the absence of paramagnetic centers in the glass [2]. The nature of this interesting phenomenon remained unclear until works [3, 4, 5, 6], where this dependence was associated with the presence of atoms with a nuclear quadrupole moment in the glass.

Owing to the interaction of the nuclear magnetic moment with the external magnetic field (Zeeman interaction) and the nuclear quadrupole moment with the gradient of the internal electric field, the levels of the TLS split into two nearly identical series of levels. The characteristic energies of such a fine structure are 10^{-21} erg (corresponding to a frequency of about 100 kHz), which are much lower than the typical energy of 50 mK of the TLS's specified by the 1 GHz frequency of the excitation pulses. Since the internal field gradient is different at different positions of the TLS's, the fine level structure depends on the tunneling state of the TLS, which ultimately leads to the nonmonotonic magnetic field dependence of the dipole echo amplitude [3, 5, 6].

As a proof of this hypothesis, the results on measuring the two-pulse echo amplitude in glycerol ($C_3H_8O_3$) were presented [4]. In this experiment the echo amplitude dependence on magnetic field increased by more than an order of magnitude under the replacement of hydrogen with zero nuclear quadrupole moment by deuterium (whose nuclear spin is 1 so deuterium has a small quadrupole moment).

The oscillations of the echo amplitude in a magnetic field were theoretically studied in [4, 5, 6, 7, 8]. In particular, the qualitative explanation of the observed effect was given in [4, 5, 6]. In [7, 8], numerical calculations of the dipole echo amplitude in glycerol in the magnetic field were performed and a good agreement with the experimental data was obtained.

In our previous work [9], we qualitatively and, in some cases, quantitatively compared our analytic expressions for the echo amplitude in glasses containing nuclear electric quadrupole moments with the experimental data. However, the existence of small oscillations of the dipole echo amplitude in glasses containing only spherical nuclei (without quadrupole moments), like in nondeuterated glycerol $C_3H_8O_3$, remained unexplained until papers [7, 8]. The presence of a small (0.037%) natural impurity of the ^{17}O isotope, which also has a nuclear quadrupole moment, did not explain these oscillations.

Fleishmann [7] suggested that the magnetic field dependence of the echo amplitude in the case of nondeuterated $C_3H_8O_3$ may be caused by the dipole-dipole interaction of the nuclear magnetic moments of hydrogen atoms (the spin and, respectively, the magnetic moment of the primary isotopes of carbon ^{12}C and oxygen ^{16}O are zero). This interaction (along with the Zeeman interaction) induces a fine structure of the levels of the TLS, which depends on the tunneling states of the systems.

Bazrafshan et al. [8] numerically calculated the echo

amplitude in deuterated glycerol $\text{C}_3\text{D}_5\text{H}_3\text{O}_3$ (taking into account all of the spins of hydrogen and the quadrupole moments of deuterium). It was assumed that the tunneling of the two-level system is the rotation of the glycerol molecule as a whole. Although the theory was in a good agreement with the experiment in high fields and in semi-quantitative agreement in low magnetic fields (when the dipole-dipole interaction is responsible for the effect), the assumption of the rotational character of tunneling was not justified.

This work is aimed at obtaining the analytical results for the magnetic field dependence of the dipole echo amplitude in the absence of nonspherical nuclei in the glass, so that only the dipole-dipole interaction of the nuclear spins is taken into account, and at comparing the results with the experimental data on non-deuterated glycerol.

II. GENERAL THEORY OF THE MAGNETIC FIELD DEPENDENCE OF THE ECHO AMPLITUDE

Parshin [6] derived a general formula specifying the dipole echo amplitude in an arbitrary system, which consists of two identical sets of levels separated by an energy gap much larger than the splitting within the sets

$$P_{\text{echo}} \propto -\frac{i}{N} V_1 V_2^2 \cdot \sum_{n,k} e^{i(E_n - E_k)\tau/\hbar} \left| \sum_m \alpha_{nm}^{(12)} \alpha_{km}^{*(12)} e^{iE_m\tau/\hbar} \right|^2. \quad (1)$$

Here, P_{echo} is the dipole echo amplitude; V_1 and V_2 are the amplitudes of the first and second exciting electric pulses, respectively; E_n are the fine-structure energy levels of the TLS, N is the total number of this levels, and $\alpha_{nm}^{(12)}$ is the matrix element for the transition between the n -th lower and m -th higher levels of the split TLS during the action of the excitation pulses.

To use this formula, we have to find the fine-structure energy levels and the matrix elements of the transition in an arbitrary magnetic field. For that, let us write the Hamiltonian of the system including, first, the tunneling of the TLS atoms and, second, the energies of the nuclear spins, which form the fine level structure:

$$\hat{H}_{\text{tot}} = \hat{H}_{\text{tls}} \otimes \hat{1}_J + \hat{1}_{\text{tls}} \otimes \hat{W}_J + \sigma_{z,\text{tls}} \otimes \hat{V}_J + (\hat{\mathbf{d}}_{\text{tls}} \mathbf{F}) \otimes \hat{1}_J. \quad (2)$$

Here $\hat{H}_{\text{tls}}$ is the Hamiltonian of the TLS in the coordinate representation (excluding the fine structure); $\hat{1}_{\text{tls}}$ and $\hat{1}_J$ are the identity matrices in the spaces of the TLS (2×2) and the nuclear spin projections, respectively; $\sigma_{z,\text{tls}}$ is the Pauli matrix for the two-level system; $\hat{\mathbf{d}}_{\text{tls}} = \mathbf{d} \sigma_{z,\text{tls}}$ is the operator of the electric dipole moment $\mathbf{d}$ of the TLS; and $\mathbf{F}$ is the external (excitation) electric field.

The spin operators $\hat{W}_J$ and $\hat{V}_J$ are, respectively, the symmetric and antisymmetric (with respect to the TLS

displacement) parts of the spin Hamiltonian

$$\hat{H}_J^{(1,2)} = \sum_i \hat{\boldsymbol{\mu}}_i \mathbf{H} + \frac{1}{2} \sum_{ij} \left[\frac{\hat{\boldsymbol{\mu}}_i \hat{\boldsymbol{\mu}}_j}{r_{ij}^3} - 3 \frac{(\hat{\boldsymbol{\mu}}_i \mathbf{r}_{ij})(\hat{\boldsymbol{\mu}}_j \mathbf{r}_{ij})}{r_{ij}^5} \right]. \quad (3)$$

Here $\hat{\boldsymbol{\mu}}_i = \mu_i \hat{\mathbf{J}}_i / J_i$ is the operator of the magnetic moment of the i -th nuclei, $\hat{\mathbf{J}}_i$ is the operator of its spin, and H is the external magnetic field. The radius vector $r_{ij} \equiv r_{ij}^{(1,2)}$ from the i -th to the j -th nuclei may depend on the TLS position (1) or (2). The summation is performed over all tunneling nuclei. Consequently,

$$\hat{W}_J = \frac{\hat{H}_J^{(1)} + \hat{H}_J^{(2)}}{2}, \quad \hat{V}_J = \frac{\hat{H}_J^{(1)} - \hat{H}_J^{(2)}}{2}. \quad (4)$$

Note that the first term of spin Hamiltonian (3), which is associated with the external magnetic field (the Zeeman part), does not include vectors $\mathbf{r}_{ij}$ that change under tunneling of the TLS and, therefore, does not contribute to the antisymmetric $\hat{V}_J$ part of the Hamiltonian. The dipole-dipole interaction (the second term of Hamiltonian (3)) enters both operators $\hat{W}_J$ and $\hat{V}_J$.

To find the quantities associated with the fine level structure, let us rewrite Hamiltonian (2) in the basis consisting of the stationary wavefunctions of the bottom and top levels of the TLS and the eigenfunctions of the operator $\hat{W}_J$ for the spin variables:

$$\begin{aligned} \hat{H}_{\text{tot}} = & \frac{1}{2} \begin{pmatrix} E & 0 \\ 0 & -E \end{pmatrix} \otimes \hat{1}_J + \hat{1}_\sigma \otimes \hat{W}_J + \\ & + (\mathbf{F} \cdot \mathbf{d}) \frac{1}{E} \begin{pmatrix} \Delta & \Delta_0 \\ \Delta_0 & -\Delta \end{pmatrix} \otimes \hat{1}_J + \\ & + \frac{1}{E} \begin{pmatrix} \Delta & \Delta_0 \\ \Delta_0 & -\Delta \end{pmatrix} \otimes \hat{V}_J. \end{aligned} \quad (5)$$

Here, Δ is the difference between the minima of the double-well potential, Δ_0 is the tunneling amplitude of the initial (unsplit) TLS, and $E = \sqrt{\Delta^2 + \Delta_0^2}$ is the total energy of the TLS (without the inclusion of the fine-structure effects). The tilded operators $\hat{W}_J$ and $\hat{V}_J$ correspond to the choice of the eigenfunctions of $\hat{W}_J$ as the basis. In this basis, $\hat{W}_J$ is a diagonal matrix.

We assume that the characteristic tunneling lengths of the nuclei are much shorter than the characteristic interatomic distances and, consequently, $\hat{V}_J$ is much smaller than $\hat{W}_J$ and may be taken into account perturbatively.

Retaining only the terms proportional to $\hat{V}_J^2$ in the transition matrix elements, we obtain the dipole echo ampli-

tude (compare with, e.g., [6])

$$P_{\text{echo}} \propto \left(\frac{\Delta_0}{E}\right)^4 \times \left[1 - \frac{64}{N} \left(\frac{\Delta}{E}\right)^2 \sum_{n,m>n} |(\tilde{V}_J)_{nm}|^2 \frac{\sin^4(\varepsilon_{nm}\tau/2\hbar)}{\varepsilon_{nm}^2}\right]. \quad (6)$$

Here, $\varepsilon_{nm} = (\tilde{W}_J)_{nn} - (\tilde{W}_J)_{mm} \equiv E_n - E_m$ is the difference between the fine-structure levels of the TLS.

Expression (6) allows one to calculate the echo amplitude from one TLS. To find the observed dipole echo amplitude of the entire sample, it is necessary to perform the summation over all two-level systems.

To obtain the expression for the distance between the fine-structure levels ε_{nm} , we have to diagonalize the matrix $\hat{W}_J$, which cannot be done analytically even in the simplest case of two interacting spins 1/2 (a 4×4 matrix). Thus, to go further, we need to perform some simplifications.

The nonmonotonic magnetic field dependence of the dipole echo amplitude in $\text{C}_3\text{H}_8\text{O}_3$ was experimentally observed in the magnetic fields $H \simeq 50$ G, which corresponds to the Zeeman energy $E_H \simeq 0.7 \times 10^{-21}$ erg. The energy of the dipole-dipole interaction between two hydrogen nuclei at a distance of 1.9 Å (the minimum distance between hydrogen atoms in glycerol) may be estimated as $E_d \simeq 1.5 \times 10^{-22}$ erg, which is almost an order of magnitude smaller than the Zeeman energy.

III. WEAK DIPOLE-DIPOLE INTERACTION APPROXIMATION

In the $E_d \ll E_H$ approximation, we neglect the dipole-dipole interaction in the expression for $\hat{W}_J$. However, this interaction should be retained in $\hat{V}_J$, which does not contain terms of the order of E_H .

In this approximation, the eigenfunctions of $\hat{W}_J$ are the states with definite projections of all nuclear spins on the direction of the magnetic field. In this case, only the matrix elements $(\tilde{V}_J)_{nm}$ of the transition with a change of no more than two spin projections are nonzero. This allows us to reduce the problem of an arbitrary number of dipole-dipole interacting nuclear spins to the problem of one pair of spins. We consider only the pairs of identical spin 1/2 nuclei. The operator $\hat{W}_J$ may be then written in the form

$$\hat{W}_J = \mu \mathbf{H}(\hat{\mathbf{J}}_1 + \hat{\mathbf{J}}_2), \quad (7)$$

where μ is the nuclear magnetic moment and $\hat{\mathbf{J}}_1$ and $\hat{\mathbf{J}}_2$ are the spin operators of the interacting nuclei. The

matrix form of $\hat{W}_J$ is

$$\hat{W}_J = \begin{pmatrix} 2\mu H & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -2\mu H \end{pmatrix}. \quad (8)$$

It is easy to see that, in this case, there are four energy differences ε_{nm} equal to $2\mu H$ and one difference $\varepsilon_{14} = 4\mu H$ (ε_{23} is zero and does not contribute to the echo amplitude).

To express the echo amplitude explicitly with the use of Eq. (6), we need to calculate also the average squares of the matrix elements $|(\tilde{V}_J)_{nm}|^2$. Taking into account the smallness of the tunneling length, the $\hat{\tilde{V}}_J$ operator in the case of two nuclei can be represented as

$$\hat{\tilde{V}}_J = \delta \mathbf{r}_{12} \cdot \frac{\partial}{\partial \mathbf{r}_{12}} \left[\frac{\hat{\boldsymbol{\mu}}_1 \hat{\boldsymbol{\mu}}_2}{r_{12}^3} - 3 \frac{(\hat{\boldsymbol{\mu}}_1 \mathbf{r}_{12})(\hat{\boldsymbol{\mu}}_2 \mathbf{r}_{12})}{r_{12}^5} \right]. \quad (9)$$

Expressing the gradient explicitly and taking out δr_{12} , r_{12} and $\hat{\boldsymbol{\mu}}_{1,2}$ as the common factors, we may rewrite Eq. (9) in the form

$$\hat{\tilde{V}}_J = \mu^2 \frac{\delta r_{12}}{r_{12}^4} \hat{\sigma}_{1,\alpha} \hat{\sigma}_{2,\beta} N_{\alpha\beta}(\mathbf{n}_r, \mathbf{n}_{\delta r}). \quad (10)$$

Here, the Greek subscripts numerate the Cartesian coordinates; $\hat{\sigma}_{1,\alpha}$ and $\hat{\sigma}_{2,\beta}$ are the Pauli matrices for the first and second spin, respectively; $N_{\alpha\beta}(\mathbf{n}_r, \mathbf{n}_{\delta r})$ is the symmetric second-rank tensor, which depends merely on the directions of the vectors $\mathbf{r}$ ($\mathbf{n}_r = \mathbf{r}/r$) and $\delta \mathbf{r}$ ($\mathbf{n}_{\delta r} = \delta \mathbf{r}/\delta r$).

To find the sought expression for $|(\tilde{V}_J)_{nm}|^2$, one has to express one matrix element from Eq. (10) and average its absolute value square over the directions of the vectors $\mathbf{n}_r$ and $\mathbf{n}_{\delta r}$ (it is easy to see that the averaging affects only the tensor $N_{\alpha\beta}$). For this purpose, we introduce a new numeration of the elements of $\hat{\tilde{V}}_J$: $(\tilde{V}_J)_{nm} = (\tilde{V}_J)_{(pr)(qs)}$. Here, the subscripts $p, q = \pm 1$ and $r, s = \pm 1$ numerate the states of the first and second spins, respectively. Correspondingly, $n = (pr)$ and $m = (qs)$. In this notation,

$$|(\tilde{V}_J)_{(pr)(qs)}|^2 = \mu^4 \frac{\delta r^2}{r^8} \times \sigma_{1,\alpha,pq} \sigma_{2,\beta,rs} \sigma_{1,\xi,pq}^* \sigma_{2,\zeta,rs}^* \langle N_{\alpha\beta} N_{\xi\zeta} \rangle. \quad (11)$$

Here, $\sigma_{1,\alpha,pq}$ is the pq element of the Pauli matrix σ_α acting on the wavefunctions of the first spin. $\sigma_{2,\beta,rs}$ is the same for the second spin.

The isotropy of the glass allows us to express the symmetric tensor $\langle N_{\alpha\beta} N_{\xi\zeta} \rangle$ in terms of two constants, $\langle N_{\alpha\beta} N_{\xi\zeta} \rangle = A \delta_{\alpha\beta} \delta_{\xi\zeta} + B(\delta_{\alpha\xi} \delta_{\beta\zeta} + \delta_{\alpha\zeta} \delta_{\beta\xi})$. However, it can be shown by direct calculation that the quantity $\sigma_{1,\alpha,pq} \sigma_{2,\beta,rs} \sigma_{1,\xi,pq}^* \sigma_{2,\zeta,rs}^* \delta_{\alpha\beta} \delta_{\xi\zeta} = |\boldsymbol{\sigma}_{1,pq} \cdot \boldsymbol{\sigma}_{2,rs}|^2$, which corresponds to the constant A , includes only the diagonal elements and the elements corresponding to the transition between the degenerate second and third levels of

FIG. 1: Experimental data on glycerol [4, 10] at (a) $\tau = 3.5 \mu\text{s}$ and (b) $8 \mu\text{s}$ in comparison with Eq. (12) with μ taken equal to the proton magnetic moment.

$\widehat{W}_J$. Neither of them contributes to the echo amplitude and, consequently, all significant matrix elements of $\widehat{V}_J$ may be expressed in terms of a single constant B .

Performing the calculations, we arrive at the final expression for the dipole echo amplitude in the form

$$P_{\text{echo}} \propto 1 - C \left[\frac{\sin^4(\mu H \tau / \hbar)}{(\mu H \tau)^2} + \frac{\sin^4(2\mu H \tau / \hbar)}{4(\mu H \tau)^2} \right], \quad (12)$$

where C is a constant independent of the magnetic field.

Note that expression (12) was derived without any assumptions about the relation between $\mathbf{n}_r$ and $\mathbf{n}_{\delta r}$ and, consequently, is absolutely independent of the tunneling geometry of the atoms, that is, of the microscopic structure of the TLS.

Let us compare Eq. (12) with the measurements [4, 10] of the magnetic field dependence of the dipole echo amplitude in glycerol (see figure). Clearly, the analytical curve with μ equal to the magnetic moment of a proton describes the experimental data sufficiently well without

any fitting parameters (except for the constant C , which specifies the vertical scale) until the region of small magnetic fields ($\leq 1 \text{ mT}$), where the conditions $E_H \ll E_d$ seemingly breaks.

A. Applicability Conditions

The nonmonotonic magnetic field dependence of the dipole echo amplitude is determined by the term $\sin^4(\varepsilon_{nm}\tau/2\hbar)$ in Eq. (6). This corresponds to the characteristic energies $\varepsilon_{nm} \simeq 2\hbar/\tau$. In the case of $E_d \ll 2\hbar/\tau$ (or, equivalently, $\tau \ll 2\hbar/E_d$), we may expect that the condition $E_d \ll E_H$ holds for the dominant part of the dependence. Otherwise, the exact inclusion of the dipole-dipole interaction is required; in this case, in particular, the problem cannot be reduced to the problem of two tunneling nuclei. This agrees well with the fact that the theory better describes the experimental data for $\tau = 3.5 \mu\text{s}$ than for $\tau = 8 \mu\text{s}$ (see figure) in the low-field region.

Note that the horizontal scale of the magnetic field dependence of the echo amplitude in the case under consideration is determined by the time τ . Thus, the curve $P_{\text{echo}}(H)$ should scale in the horizontal axis as $1/\tau$ with a change in the time interval between the pulses. In the opposite case of $\tau \gtrsim 2\hbar/E_d$, the horizontal scale of the dependence is determined by the relation $E_d \simeq E_H$ and is independent of the time interval between the pulses. This may be used as an experimental criterion of the smallness of the dipole-dipole interaction.

To conclude, in the experimentally observed case of $\tau \ll 2\hbar/E_d$, the magnetic field dependence of the dipole echo amplitude induced by the dipole-dipole interaction of the nuclei of the same kind has a universal character independent of the microscopic structure of the TLS. It is well described by a simple analytic expression. A good agreement of the theory and experiment on the dipole echo in nondeuterated glycerol was obtained without any fitting parameter (except for the echo amplitude scale). At larger values of the time interval between the excitation pulses, $\tau \gtrsim 2\hbar/E_d$, the universal form of the dependence breaks, which may allow one to obtain information on the microscopic structure of the two-level systems with the use of numerical analysis [11].

We are grateful to A. Fleishmann and M. Bazrafshan for fruitful discussions.
